### Contents

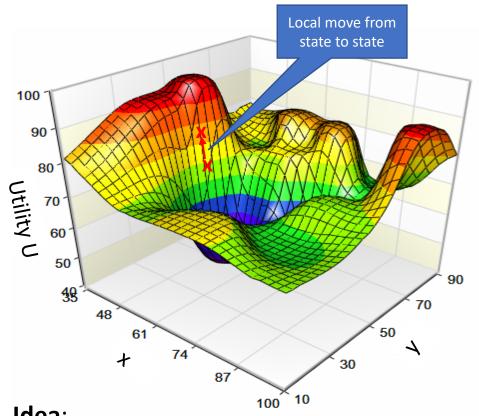

### Recap: Uninformed and Informed Search

Tries to plan the best path from a given initial state to a given goal state.

- Often comes with optimality guarantees (BFS, A\* Search, IDS).
- Typically searches a large portion of the search space (needs time and memory).

# Local Search Algorithms

 What if we do not know the goal state, but the utility of different states is given by a utility function U = u(s)?

• We use a factored state description. Here 
$$s = (x, y)$$

- We could try to identify the best or at least a "good" state?
- This is the **optimization problem**:  $s^* = \operatorname{argmax} u(s)$  $s \in S$
- We need a fast and memoryefficient way to find the best/a good state.

Idea:

Start with a current solution (a state) and improve the solution by moving from the current state to a "neighboring" better state (a.k.a. performing a series of local moves).

## Local Search Algorithms

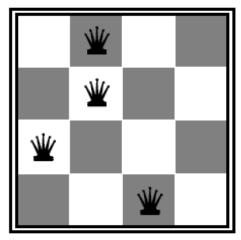

### Difference to search from the previous chapter:

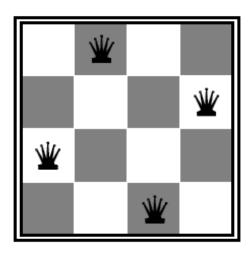

- a) Goal state is unknown, but we know or can calculate the utility for each state. We want to identify the state with the highest utility.
- b) Often no explicit initial state + path to goal and path cost are not important.
- c) No search tree. Just stores the current state and move to a "better" state if possible.

#### Use in Al

- Goal-based agent: Identify a good goal state with a good utility before planning a path to that state.
- Utility-based agent: Always move to a neighboring state with higher utility. A simple greedy method used for
  - complicated/large state spaces or
  - online search.
- **General optimization**: u(s) can be replaced by a general objective function. Local search is an effective heuristic to find good solutions in large or continuous search spaces. E.g., stochastic gradient descend to train neural networks learns to approximate a function by using the prediction error as the objective function.

#### states

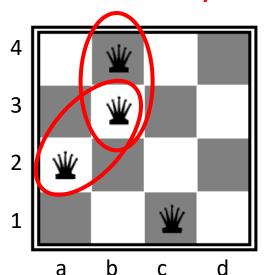

# Example: n-Queens Problem

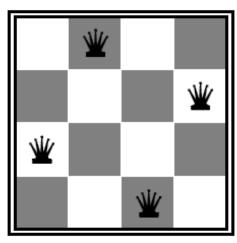

**Goal**: Put n queens on an  $n \times n$  board with no two queens on the same row, column, or diagonal.

### **Defining the search problem:**

- **State space:** All possible *n*-queen configurations. How many are there?
- **State representation:** How do we define a factored representation?
- Objective function: What is a possible utility function given the state representation?
- Local neighborhood: What states are close to each other?

### 2 conflicts = utility of -2

0 conflicts = utility of 0

# Example: n-Queens Problem

### **Defining the search problem:**

- State space: All possible *n*-queen configurations. How many are there? 4-queens problem:  $\binom{16}{4} = 1820$
- State representation: How do we define a factored representation?
   E.g. (a2, b3, b4, c1)
- Objective function: What is a possible utility function given the state representation?
   Maximizing utility means minimize the number of pairwise conflicts based on the state representation.

Has its optimum at the goal state. Similar to a heuristic in A\* search.

 Local neighborhood: What states are close to each other? Move a single queen.

Defines a transition function.

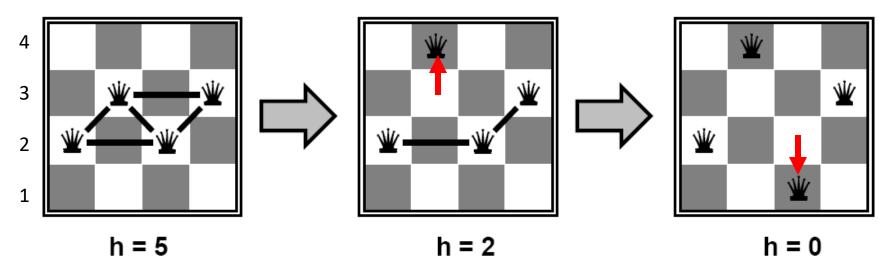

## Example: n-Queens Problem

- Goal: Put n queens on an  $n \times n$  board with no two queens on the same row, column, or diagonal.
- **State space:** all possible *n*-queen configurations. We can restrict the state space: Only one queen per column.
- State representation: row position of each queen in its column (e.g., 2, 3, 2, 3)
- Objective function: minimize the number of pairwise conflicts.
- Local neighborhood: Move one queen anywhere in its column.

State space is reduced from 1820 to  $4^4 = 256$ 

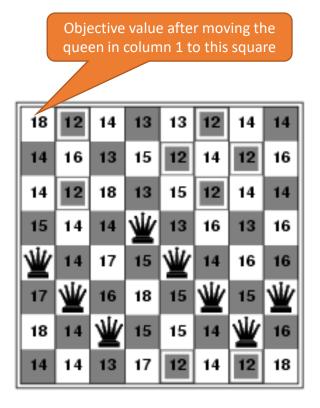

#### Improvement strategy

Find a local neighboring state (move one queen within its column) to reduce conflicts

## Example: n-Queens Problem

To find the best local move, we must evaluate all local neighbors (moving a single queen in its column while leaving the others in place) and calculate the objective function.

Current objective value: h = 17Best local improvement has h = 12

#### Notes:

- There are many options with h=12. We must choose one!
- Calculating all the objective values may be expensive!

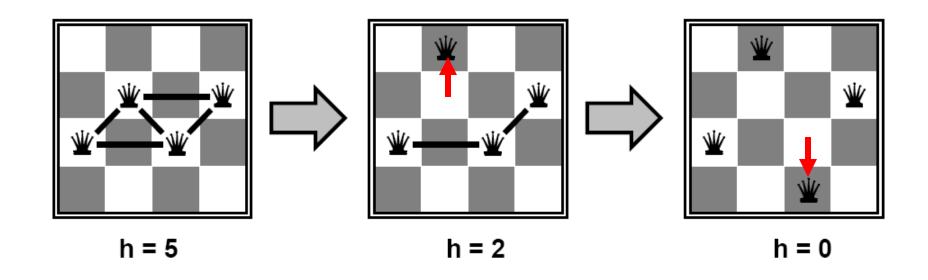

# Example: n-Queens Problem

Formulation as an optimization problem: Find the best state  $s^*$  representing an arrangement of queens.

$$s^* = \operatorname{argmin}_{s \in S} \operatorname{conflicts}(s)$$

subject to: s has one queen per column

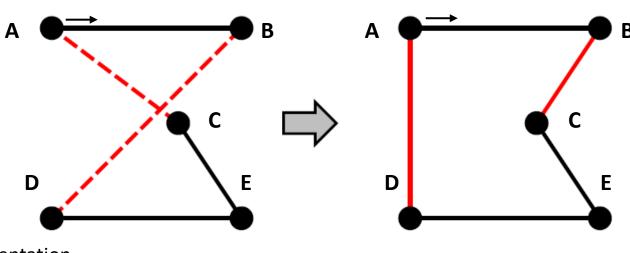

Remember: This makes the problem a lot easier.

Example: Traveling Salesman Problem

- Goal: Find the shortest tour connecting n cities
- State space: all possible tours
- **State representation:** tour (order in which to visit the cities) = a permutation. There are n! Many permutations.
- Objective function: length of tour
- Local neighborhood: reverse the order of visiting a few cities

Local move to reverse the order of cities C, E and D:

State representation (permutation):

**ABDEC** 

**ABCED** 

## Example: Traveling Salesman Problem

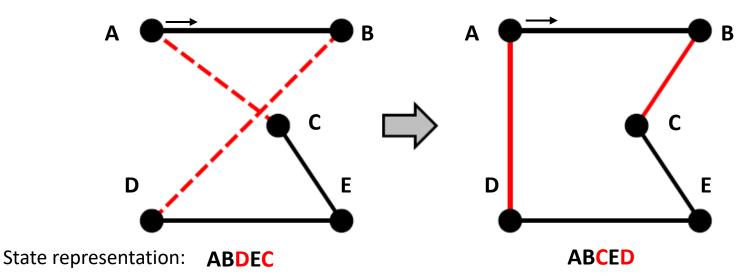

s.t.  $\pi$  is a valid permutation (i.e., sub-tour elimination)

# Formulation as an optimization problem: Find the best tour $\pi$

 $\pi^* = \operatorname{argmin}_{\pi} \operatorname{tourLength}(\pi)$ 

s.t.  $\pi$  is a valid permutation (i.e., sub-tour elimination)

Local move to reverse the order of cities C, E and D:

### Hill-Climbing Search (Greedy Local Search)

**function** HILL-CLIMBING(problem) **returns** a state that is a local maximum  $current \leftarrow problem.$ INITIAL We often start with a random state **while** true **do**  $neighbor \leftarrow \text{a highest-valued successor state of } current$   $if \text{ VALUE}(neighbor) \leq \text{VALUE}(current) \text{ then return } current$   $current \leftarrow neighbor$ 

Use  $\geq$  for minimization

#### Variants:

### Steepest-ascend hill climbing

 Check all possible successors and choose the highestvalued successors.

### Stochastic hill climbing

- Choose randomly among all uphill (improvement) moves, or
- generate randomly one new successor at a time and only move to better ones = first-choice hill climbing – the most popular variant, this is what people often mean when they say "stochastic hill climbing"

### Minimization

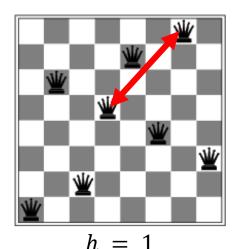

Maximization

## Local Optima

Hill-climbing search is like greedy best-first search with the objective function as a (maybe not admissible) heuristic and no frontier (just stops in a dead end).

### Is it complete/optimal?

No – can get stuck in local optima

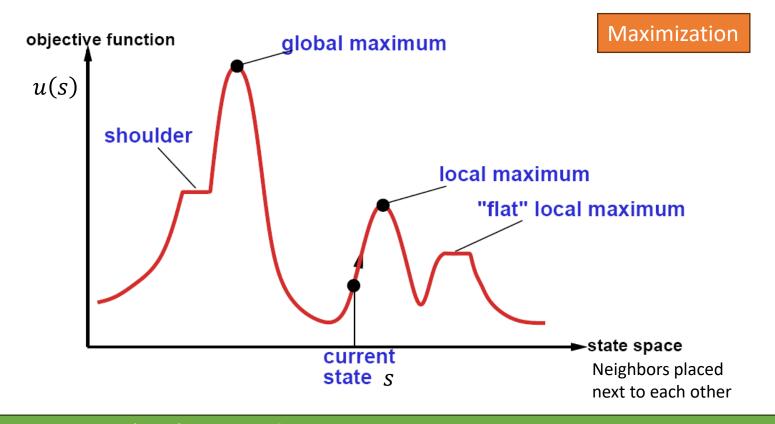

Example: local optimum for the 8queens problem. No single queen can be moved within its column to improve the objective function.

Simple approach that can help with local optima:

**Random-restart hill climbing:** Restart hill-climbing many times with random initial states and return the best solution. This strategy can be used for any stochastic (i.e., randomized) algorithm.

# The State Space "Landscape"

We can get the utility (objective function value) from the state description using u(s).

How to escape local maxima?

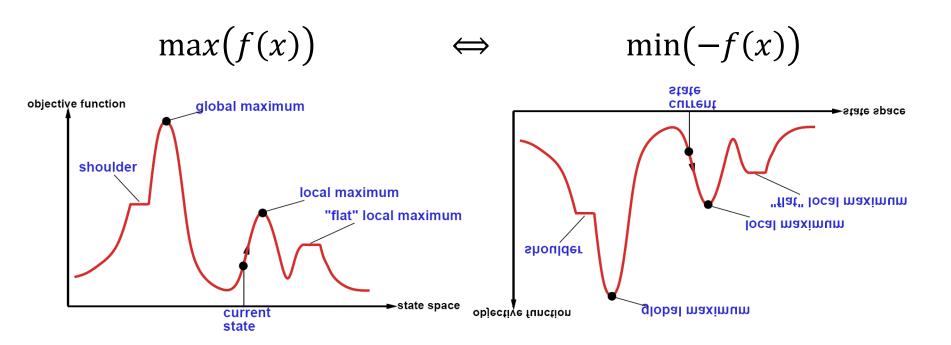

→ Random restart hill-climbing can help.

What about "shoulders" (called "ridges" in higher dimensional space)?

→ Hill-climbing that allows sideways moves and uses momentum.

### Minimization vs. Maximization

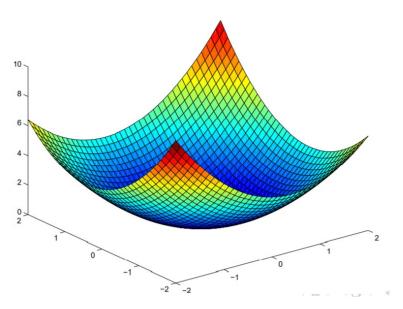

- The name hill climbing used in AI implies maximizing a function.
- Optimizers like to state problems as minimization problems and call hill climbing gradient descent instead.
- Both types of problems are equivalent:

### Convex vs. Non-Convex Optimization Problems

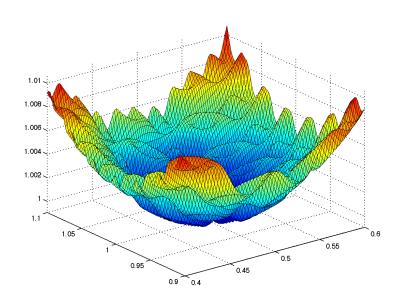

Minimization

#### **Convex Problem**

One global optimum + continuous smooth function  $\rightarrow$  calculus makes it easy (solve f'(x) = 0)

#### Non-convex Problem

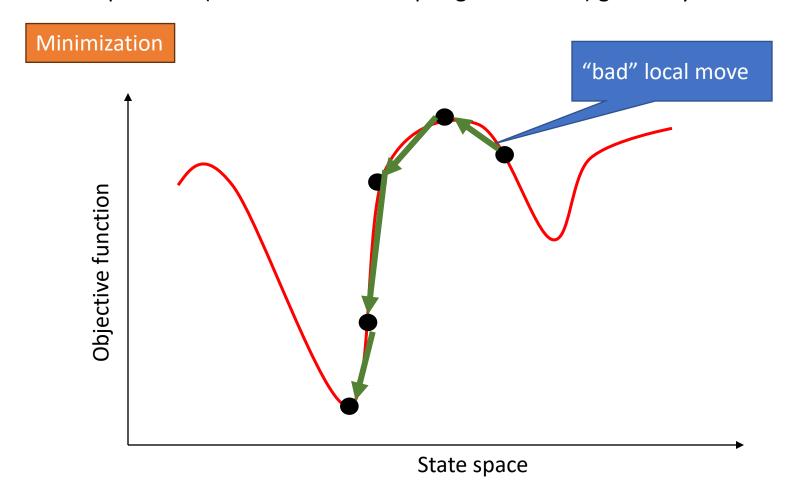

Many local optima → hard

Many AI problems are in addition discrete (the objective function is not differentiable). We often have to settle for a local optimum.

## Simulated Annealing

- Idea: First-choice stochastic hill climbing + escape local minima by allowing some "bad" moves but gradually decrease their frequency.
- Inspired by the process of controlled cooling of glass or metals by decreasing the temperature (here chance of accepting bad moves) gradually.

## Simulated Annealing

- **Idea**: First-choice stochastic hill climbing + escape local minima by allowing some "bad" moves but gradually decreasing their frequency as we get closer to the solution.
- Annealing tries to reach a low energy state so a negative  $\Delta E$  means the solution gets better.
- The probability of accepting "bad" moves follows the annealing schedule that reduces the temperature T over time t.

Maximization

```
function SIMULATED-ANNEALING(problem, schedule) returns a solution state
   current \leftarrow problem.INITIAL
                                          Typically, we start with a random state
   for t = 1 to \infty do
       T \leftarrow schedule(t)
       if T = 0 then return current
       next \leftarrow a randomly selected successor of current
       \Delta E \leftarrow \text{VALUE}(current) - \text{VALUE}(next)
       if \Delta E < 0 then current \leftarrow next
       else current \leftarrow next only with probability e^{-\Delta E/T}
```

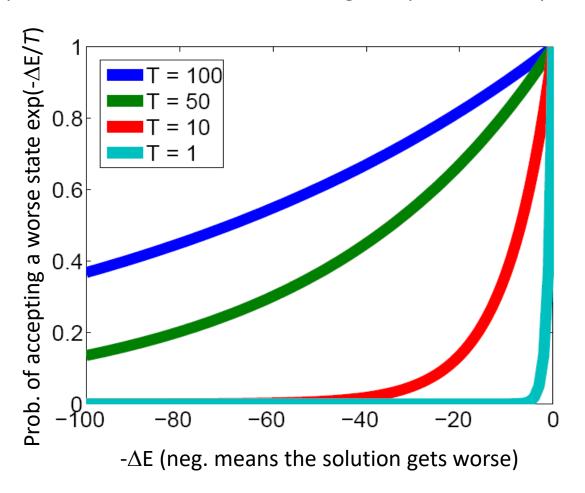

Always accept good moves that reduce the energy.

Accept "bad" moves with a probability inspired by the acceptance criterion in the Metropolis-Hastings MCMC algorithm.

Note: Use *VALUE*(*next*) – *VALUE*(*current*) for minimization

## The Effect of Temperature

Convert the changes due to "bad" moves into an acceptance probability depending on the temperature. The criterion uses the negative part of the exponential function.

# Cooling Schedule

The cooling schedule is very important. Popular schedules for the temperature at time *t*:

- Classic simulated annealing:  $T_t = T_0 \frac{1}{\log(1+t)}$
- Exponential cooling (Kirkpatrick, Gelatt and Vecchi; 1983)

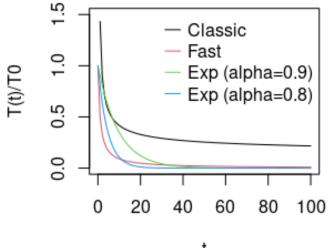

$$T_t = T_0 \alpha^t$$
 for  $0.8 < \alpha < 1$ 

Fast simulated annealing (Szy and Hartley; 1987)

$$T_t = T_0 \frac{1}{1+t}$$

#### Notes:

- Choose  $T_0$  to provide a high probability  $p_0 = e^{-\frac{2\pi}{T_0}}$  that any move will be accepted at time t=0.  $\Delta E$  is determined by the worst possible move.
- $T_t$  will not become 0 but very small. Stop when  $T < \epsilon$  ( $\epsilon$  is a very small constant).
- The best schedule (cooling rate) is typically determined by trial-and-error. The goal is to have a low chance of getting stuck in a local optima.

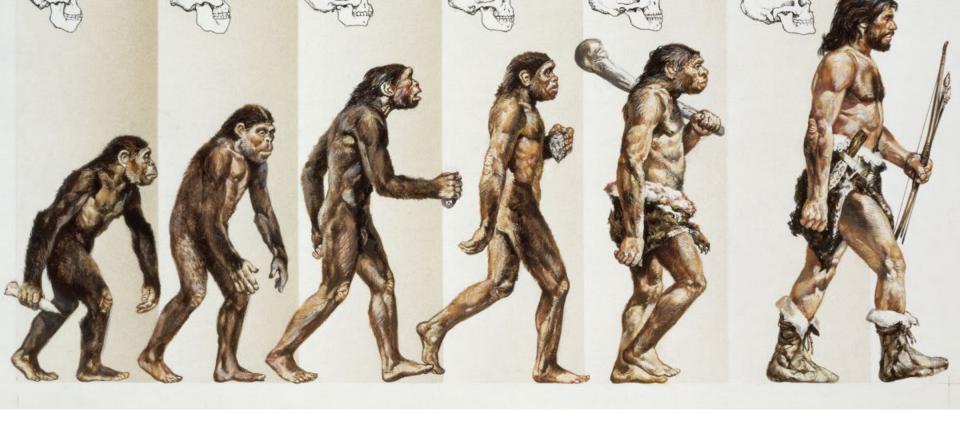

# Simulated Annealing Search

**Guarantee:** If the temperature is decreased **slowly enough**, then simulated annealing search will find a global optimum with a probability approaching one.

### However:

- This usually takes impractically long.
- We need to experiment with the cooling schedule to find one that typically avoids local optima.

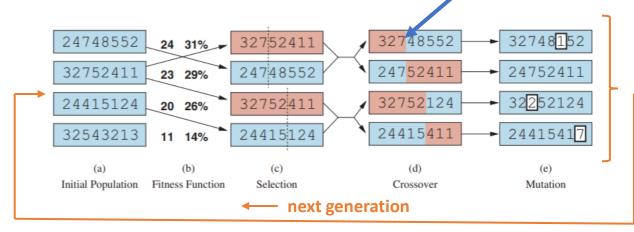

# Evolutionary Algorithms

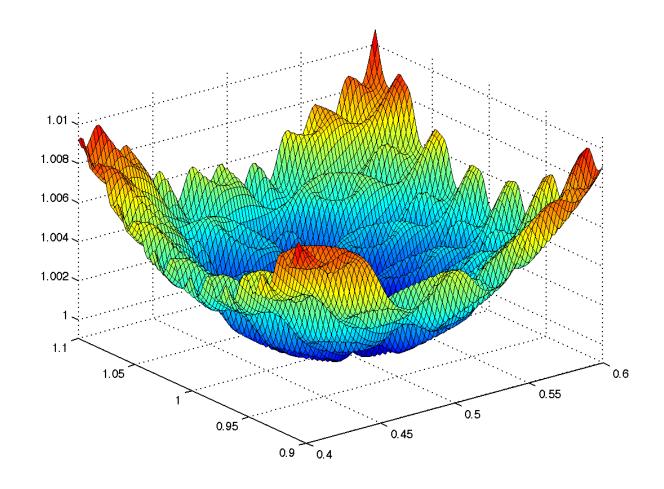

A Population-based Metaheuristics

### Evolutionary Algorithms / Genetic Algorithms

- A metaheuristic for population-based optimization.
- Uses mechanisms inspired by biological evolution (genetics):
  - Reproduction: Random selection with probability based on a fitness function.
  - Random recombination (crossover)
  - Random mutation
  - Repeated for many generations
- Example: 8-queens problem

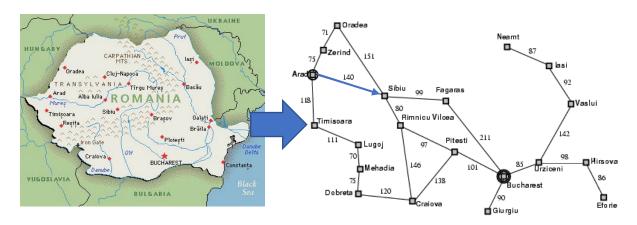

representation as
 a chromosome:
row of the queen
in each column

## Search in Continuous Spaces

### Discretization of Continuous Space

Use atomic states and create a graph as the transition function.

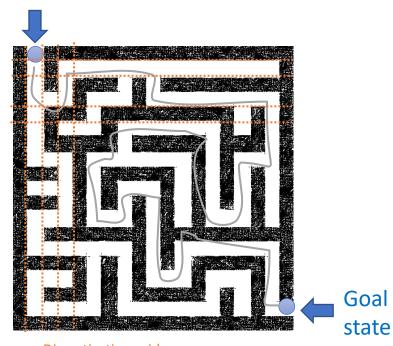

• Use a grid with spacing of size  $\delta$  Note: You probably need a way finer grid!

### Discretization of Continuous Space

### How did we discretize this space?

Initial state

····· Discretization grid

Search in Continuous Spaces:

**Gradient Descent** 

State representation:  $x = (x_1, x_2, ..., x_k)$ 

State space size: infinite

**Objective function**: min  $f(x) = f(x_1, x_2, ..., x_k)$ 

**Local neighborhood**: small changes in  $x_1, x_2, ..., x_k$ 

Gradient at point 
$$\mathbf{x}$$
:  $\nabla f(\mathbf{x}) = \left(\frac{\partial f(\mathbf{x})}{\partial x_1}, \frac{\partial f(\mathbf{x})}{\partial x_2}, ..., \frac{\partial f(\mathbf{x})}{\partial x_k}\right)$ 

(=evaluation of the Jacobian matrix at x)

Find optimum by solving:  $\nabla f(x) = 0$ 

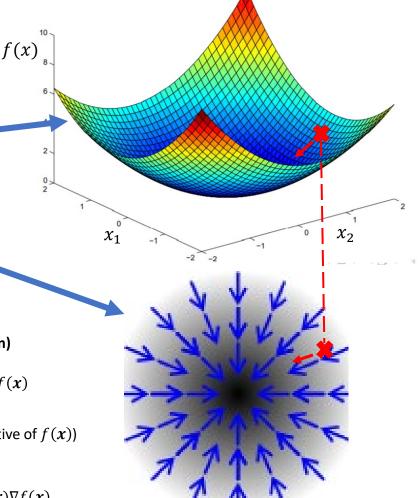

Repeat: 
$$x \leftarrow x - \alpha \nabla f(x)$$

#### Newton-Raphson method

uses the inverse of the Hessian matrix (second-order partial derivative of f(x))

$$H_{ij} = \frac{\partial^2 f}{\partial x_i \partial x_j}$$
 as the optimal step size

Repeat: 
$$\mathbf{x} \leftarrow \mathbf{x} - \mathbf{H}_f^{-1}(\mathbf{x}) \nabla f(\mathbf{x})$$

Note: May get stuck in a local optimum if the search space is non-convex! Use simulated annealing, momentum or other methods to escape local optima.

## Search in Continuous Spaces: Stochastic Gradient Descent

- What if the mathematical formulation of the objective function is not known?
- We may have objective values at fixed points, called the **training data**.
- In this case, we can perform gradient descent with an approximation of the gradient using the data points. This is called **stochastic gradient descent (SGD).**

→ We will talk more about search in continuous spaces with loss functions using gradient descend when we talk about parameter learning for learning from examples (machine learning).

### Conclusion

- Local search provides a fast method to find good solutions to many difficult optimization problems.
- Local optima are a big issue that can be addressed with random restarts and simulated annealing.
